Examples

```
## -----
## load data
## -----

library(healthyFlowData)
data(hd)

## -----
## Retrieve each sample, cluster it and store the
## clustered samples in a list
## -----
set.seed(1234) # for reproducible clustering
cat('Clustering samples: ')
clustSamples = list()
for(i in 1:length(hd.flowSet))
{
  cat(i, ' ')
  sample1 = exprs(hd.flowSet[[i]])
  clust1 = kmeans(sample1, centers=4, nstart=20)
  cluster.labels1 = clust1$cluster
  clustSample1 = ClusteredSample(labels=cluster.labels1, sample=sample1)
  clustSamples = c(clustSamples, clustSample1)
}

## -----
## Create a template from the list of clustered samples and plot functions
## -----

template = create.template(clustSamples)
summary(template)

## plot the tree denoting the hierarchy of the samples in a template
tree = template.tree(template)

## plot the template in terms of the meta-clusters
## option-1 (default): plot contours of each cluster of the meta-clusters
plot(template)
```

Cluster-class

Cluster: A class representing a cell population in FC

Description

An object of class "Cluster" represents a cluster or a cell population. We model a cluster with a normal distribution. An object of class "Cluster" therefore represents a cluster with a mean vector, a covariance matrix and the size of the cluster.

Creating Object

An object of class `Cluster` is usually created when constructing an object of class `ClusteredSample`. Unless you know exactly what you are doing, creating an object of class "Cluster" using `new` or using the constructor is discouraged.

An object of class "Cluster" can be created using the following constructor

```
Cluster(size, center, cov, cluster.id = NA_integer_, sample.id = NA_integer_)
```

The arguments of the constructor bear usual meaning as described in the value section above.

Slots

An object of class "Cluster" contains the following slots:

`size`: An integer denoting the number of points (cells) present in the cluster.

`center`: A numeric vector denoting the center of the cluster.

`cov`: A matrix denoting the covariances of the underlying normal distribution of the cluster.

`cluster.id`: The index of the cluster (relative to other clusters in same sample). Default is `NA_integer_`.

`sample.id`: The index of sample in which the cluster belongs to. Default is `NA_integer_`.

Accessors

All the slot accessor functions take an object of class `Cluster`. I show usage of the first accessor function. Other functions can be called similarly.

Returns the number of cells in the cluster.

Usage: `get.size(object)`

here `object` is a `Cluster` object.

`get.size`: Returns the center of the cluster.

`get.cov`: Returns the covariances matrix of the cluster.

`get.cluster.id`: Returns the index of the cluster (relative to other clusters in same sample).

`get.sample.id`: Returns the index of sample in which the cluster belongs to.

`sample.id<-`: Set the index of sample in which the cluster belongs to.

Methods

show Display details about the `Cluster` object.

summary Return descriptive summary for each `Cluster` object.

Usage: `summary(Cluster)`

ClusteredSample-class *ClusteredSample: A class representing a clustered FC Sample*

Description

An object of class "ClusteredSample" represents a partitioning of a sample into clusters. We model a flow cytometry sample with a mixture of cell populations where a cell population is a normally distributed cluster. An object of class "ClusteredSample" therefore stores a list of clusters and other necessary parameters.

Creating Object

An object of class "ClusteredSample" can be created using the following constructor

```
ClusteredSample(labels, centers=list(), covs=list(), sample=NULL, sample.id=NA_integer_)
```

- **labels** A vector of integers (from 1:num.clusters) indicating the cluster to which each point is allocated. This is usually obtained from a clustering algorithm.
- **centers** A list of length num.clusters storing the centers of the clusters. The ith entry of the list centers[[i]] stores the center of the ith cluster. If not specified, the constructor estimates centers from sample.
- **covs** A list of length num.clusters storing the covariance matrices of the clusters. The ith entry of the list cov[[i]] stores the covariance matrix of the ith cluster. If not specified, the constructor estimates cov from sample.
- **sample** A matrix, data frame of observations, or object of class flowFrame. Rows correspond to observations and columns correspond to variables. It must be passed to the constructor if either centers or cov is unspecified; then centers or cov is estimated from sample.
- **sample.id** The index of the sample (relative to other samples of a cohort).

Slots

An object of class "ClusteredSample" contains the following slots:

The number of clusters in the sample.

num.clusters **labels** A vector of integers (from range 1:num.clusters) indicating the cluster to which each point is assigned to. For example, labels[i]=j means that the ith element (cell) is assigned to the jth cluster.

dimension Dimensionality of the sample (number of columns in data matrix).

clusters A list of length num.clusters storing the cell populations. Each cluster is stored as an object of class [Cluster](#).

size Number of cells in the sample (summation of all cluster sizes).

sample.id integer, denoting the index of the sample (relative to other samples of a cohort). Default is NA_integer_

Accessors

All the slot accessor functions take an object of class ClusteredSample. I show usage of the first accessor function. Other functions can be called similarly.

Returns the number of cells in the sample (summation of all cluster sizes).

Usage: get.size(object)

here object is a ClusteredSample object.

get.size: num.clusters Returns the number of clusters in the sample.

get.labels Returns the cluster labels for each cell. For example, labels[i]=j means that the ith element (cell) is assigned to the jth cluster.

get.dimension Returns the dimensionality of the sample (number of columns in data matrix).

get.clusters Returns the list of clusters in this sample. Each cluster is stored as an object of class [Cluster](#).

get.sample.id Returns the index of the sample (relative to other samples of a cohort).

Methods

show Display details about the ClusteredSample object.

summary Return descriptive summary for the ClusteredSample object.

Usage: summary(ClusteredSample)

plot We plot a sample by bivariate scatter plots where different clusters are shown in different colors.

Usage:

plot(sample, ClusteredSample, ...)

the arguments of the plot function are:

- **sample:** A matrix, data.frame or an object of class flowFrame representing an FC sample.
- **ClusteredSample:** An object of class ClusteredSample storing the clustering of the sample.
- **...** Other usual plotting related parameters.

ClusterMatch-class	<i>ClusterMatch: A class representing matching of cluster/meta-clusters across a pair of FC samples/templates</i>
--------------------	---

Description

An object of class "ClusterMatch" represents matching of cluster/meta-clusters across a pair of FC samples/templates. A cluster (meta-cluster) from a sample (template) can match to zero, one or more than one cluster (meta-clusters) in another sample (template).

Creating Object

An object of class "ClusterMatch" is usually created by calling the function `match.clusters`:

```
match.clusters(object1, object2, dist.type='Mahalanobis', unmatched.penalty=999999).
```

Here, object1 and object2 are two objects of class `ClusteredSample` or `Template` between which the clusters or meta-clusters are matched. See the example section and also the `match.clusters` function for more details.

Unless you know exactly what you are doing, creating an object of class "ClusterMtach" using `new` or using the constructor is discouraged.

Slots

Let S1 and S2 be two FC samples or templates with k1 and k2 clusters or meta-clusters respectively. Then the matching of clusters (meta-clusters) across S1 and S2 is represented by an object of class "ClusterMatch" that contains the following slots:

match12: A list of length k1 where match12[[i]] stores the indices of clusters (meta-clusters) from S2 matched to the i-th cluster (meta-cluster) of S1. match12[[i]]=NULL if the i-th cluster (meta-cluster) of S1 remains unmatched, otherwise, it stores a vector of matched clusters (meta-clusters) from S2.

match21: A list of length k2 where match21[[i]] stores the indices of clusters (meta-clusters) from S1 matched to the i-th cluster (meta-cluster) of S2. match21[[i]]=NULL if the i-th cluster (meta-cluster) of S2 remains unmatched, otherwise, it stores a vector of matched clusters (meta-clusters) from S1.

matching.cost: The cost of matching clusters (meta-clusters) across the samples. It is equal to the summation of dissimilarities of the matched clusters (meta-clusters) and penalty for the unmatched clusters (meta-clusters).

unmatch.penalty: A numeric value denoting the penalty for leaving a cluster (meta-cluster) unmatched. If we set it to a very large value then no cluster (meta-cluster) remains unmatched giving an edge cover solution.

Accessors

All the slot accessor functions take an object of class ClusterMatch. I show usage of the first accessor function. Other functions can be called similarly.

Returns the matching from cluster in sample 1 to clusters in sample 2. See the slot description for details. *Usage:* get.match12(object)

here object is a ClusterMatch object.

get.match21: Returns the matching from cluster in sample 2 to clusters in sample 1. See the slot description for details.

get.matching.cost: Returns the total cost of matching clusters (meta-clusters) across the pair samples/templates.

get.unmatch.penalty: Returns the penalty for leaving a cluster (meta-cluster) unmatched.

Methods

show Display details about the ClusterMatch object.

summary Return descriptive summary of the matching of clusters (meta-clusters) across a pair of samples (templates). Shows both list and matrix format.

Usage: summary(ClusterMatch)

create.template	<i>Creating a template of a collection of FC samples</i>
-----------------	--

Description

Create an object of class [Template](#) summarizes a group of samples belonging to same biological-class with a class-template. A template is represented by a collection of meta-clusters ([MetaCluster](#)) created from samples of same class. An object of class [Template](#) therefore stores a list of [MetaCluster](#) objects and other necessary parameters.

Usage

```
create.template(clustSamples, dist.type = "Mahalanobis", unmatched.penalty=999999, template.id = NA_in
```

Arguments

clustSamples	A list of ClusteredSample objects from which the template is created. The working examples describe how this objects are created by clustering FC samples.
--------------	--

<code>dist.type</code>	character, indicating the method with which the dissimilarity between a pair of clusters is computed. Supported dissimilarity measures are: 'Mahalanobis', 'KL' and 'Euclidean'. If this argument is not passed then 'Mahalanobis' distance is used by default.
<code>unmatch.penalty</code>	A numeric value denoting the penalty for leaving a cluster unmatched. This parameter should be already known or be estimated empirically estimated from data (see the reference for a discussion). Default is set to a very high value so that no cluster remains unmatched.
<code>template.id</code>	integer, denoting the index of the template (relative to other template). Default is NA_integer_

Details

An object of class [Template](#) summarizes a group of samples belonging to same biological-class with a class-specific template. A template is represented by a collection of meta-clusters ([MetaCluster](#)) created from samples of same class. An object of class [Template](#) therefore stores a list of [MetaCluster](#) objects and other necessary parameters.

Value

`dist.sample` returns a numeric value representing dissimilarity between a pair of samples. This value is equal to the summation of dissimilarities of the matched clusters and penalty for the unmatched clusters.

```

dist.cluster

Dissimilarity between a pair of clusters

Description

Calculate the dissimilarity between a pair of cell populations (clusters) from the distributions of the clusters.

Usage

```
dist.cluster(cluster1, cluster2, dist.type = 'Mahalanobis')
```

Arguments

cluster1	an object of class <code>Cluster</code> representing the distribution parameters of the first cluster.
cluster2	an object of class <code>Cluster</code> representing the distribution parameters of the second cluster.
dist.type	character, indicating the method with which the dissimilarity between a pair of clusters is computed. Supported dissimilarity measures are: 'Mahalanobis', 'KL' and 'Euclidean'.

Details

Consider two p-dimensional, normally distributed clusters with centers μ_1, μ_2 and covariance matrices Σ_1, Σ_2 . Assume the size of the clusters are n_1 and n_2 respectively. We compute the dissimilarity d_{12} between the clusters as follows:

1. If `dist.type='Mahalanobis'`: we compute the dissimilarity d_{12} with the Mahalanobis distance between the distributions of the clusters.

$$\Sigma = ((n_1 - 1) * \Sigma_1 + (n_2 - 1) * \Sigma_2) / (n_1 + n_2 - 2)$$

$$d_{12} = \text{sqrt}(t(\mu_1 - \mu_2) * \Sigma^{-1} * (\mu_1 - \mu_2))$$

2. If `dist.type='KL'`: we compute the dissimilarity d_{12} with the Symmetrized Kullback-Leibler divergence between the distributions of the clusters. Note that KL-divergence is not symmetric in its original form. We converted it symmetric by averaging both way KL divergence. The symmetrized KL-divergence is not a metric because it does not satisfy triangle inequality.

$$d_{12} = 1/4 * (t(\mu_2 - \mu_1) * (\Sigma_1^{-1} - 1) + \Sigma_2^{-1} - 1) * (\mu_2 - \mu_1) + \text{trace}(\Sigma_1 / \Sigma_2 + \Sigma_2 / \Sigma_1) + 2p)$$

3. If `dist.type='Euclidean'`: we compute the dissimilarity d_{12} with the Euclidean distance between the centers of the clusters.

$$d_{12} = \text{sqrt}(\sum (\mu_1 - \mu_2)^2)$$

The dimension of the clusters must be same.

Value

`dist.cluster` returns a numeric value denoting the dissimilarities between a pair of cell populations (clusters).

dist.matrix	<i>Dissimilarity matrix between each pair of clusters/meta-clusters across a pair of samples/templates</i>
-------------	--

Description

Calculate a matrix storing the dissimilarities between each pair of clusters (meta-clusters) across a pair of samples (templates) S1 and S2. (i, j)th entry of the matrix stores dissimilarity between i-th cluster (meta-cluster) from S1 and the j-th cluster (meta-cluster) from S2.

Usage

```
dist.matrix(object1,object2, dist.type = 'Mahalanobis')
```

Arguments

object1	an object of class ClusteredSample or Template .
object2	an object of class ClusteredSample or Template .
dist.type	character, indicating the method with which the dissimilarity between a pair of clusters (meta-clusters) is computed. Supported dissimilarity measures are: 'Mahalanobis', 'KL' and 'Euclidean', with the default is set to 'Mahalanobis' distance.

Details

Consider two FC samples/templates S1 and S2 with k1 and k2 clusters/meta-clusters. The dissimilarity between each pair of cluster (meta-clusters) across S1 and S2 is computed and stored in a (k1 x k2) matrix. The dissimilarity between i-th cluster (meta-cluster) from S1 and j-th cluster (meta-cluster) from S2 is computed using function [dist.cluster](#).

Value

`dist.matrix` function returns a (k1 x k2) matrix where k1 and k2 are the number of clusters (meta-clusters) in the first and the second samples (templates) respectively. (i, j)th entry of the matrix contains the dissimilarity between the i-th cluster (meta-cluster) from sample1 (template1) and the j-th cluster (meta-cluster) from sample2 (template2).

dist.sample

Dissimilarity between a pair of clustered FC samples

Description

Compute the dissimilarity between a pair of clustered FC samples by using Mixed Edge Cover (MEC) algorithm.

Usage

```
dist.sample(clustSample1, clustSample2, dist.type='Mahalanobis', unmatched.penalty=999999)
```

Arguments

clustSample1	an object of class ClusteredSample containing cell populations from sample 1.
clustSample2	an object of class ClusteredSample containing cell populations from sample 2.
dist.type	character, indicating the method with which the dissimilarity between a pair of clusters is computed. Supported dissimilarity measures are: 'Mahalanobis', 'KL' and 'Euclidean'.
unmatched.penalty	A numeric value denoting the penalty for leaving a cluster unmatched. This parameter should be already known or be estimated empirically estimated from data (see the reference for a discussion). Default is set to a very high value so that no cluster remains unmatched.

Details

We used a robust version of matching called Mixed Edge Cover (MEC) to match clusters across a pair of samples. MEC allows a cluster to be matched with zero, one or more than one clusters in a paired sample. The cost of an MEC solution is equal to the summation of dissimilarities of the matched clusters and penalty for the unmatched clusters. The MEC algorithm finds an optimal solution by minimizing the cost of MEC, which is then used as dissimilarity between a pair of samples.

Value

`dist.sample` returns a numeric value representing dissimilarity between a pair of samples. This value is equal to the summation of dissimilarities of the matched clusters and penalty for the unmatched clusters.

```

Arguments

template1	an object of class Template containing cell populations from template 1.
template2	an object of class Template containing cell populations from template 2.
dist.type	character, indicating the method with which the dissimilarity between a pair of meta-clusters is computed. Supported dissimilarity measures are: 'Mahalanobis', 'KL' and 'Euclidean'.
unmatched.penalty	A numeric value denoting the penalty for leaving a meta-cluster unmatched. This parameter should be already known or be estimated empirically estimated from data (see the reference for a discussion). Default is set to a very high value so that no meta-cluster remains unmatched.

Details

We used a robust version of matching called Mixed Edge Cover (MEC) to match meta-clusters across a pair of templates. MEC allows a meta-cluster to be matched with zero, one or more than one meta-clusters in a paired template. The cost of an MEC solution is equal to the summation of dissimilarities of the matched meta-clusters and penalty for the unmatched meta-clusters. The MEC algorithm finds an optimal solution by minimizing the cost of MEC, which is then used as dissimilarity between a pair of templates.

Value

dist.template returns a numeric value representing dissimilarity between a pair of templates. This value is equal to the summation of dissimilarities of the matched meta-clusters and penalty for the unmatched meta-clusters.

## Create two templates each from five samples
## -----

template1 = create.template(clustSamples[1:5])
template2 = create.template(clustSamples[6:10])

D = dist.template(template1, template2, dist.type='Mahalanobis', unmatched.penalty=999999)
```

Description

Compute the Mahalanobis distance between a pair of normally distributed clusters.

Usage

```
mahalanobis.dist(mean1, mean2, cov1, cov2, n1, n2)
```

Arguments

mean1	mean vector of length p for cluster 1, where p is the dimension of the clusters.
mean2	mean vector of length p for cluster 2.
cov1	pxp covariance matrix for cluster 1.
cov2	pxp covariance matrix for cluster 2.
n1	number of cells (points) in cluster 1.
n2	number of cells (points) in cluster 2.

Details

Consider two p-dimensional, normally distributed clusters with centers μ_1, μ_2 and covariance matrices Σ_1, Σ_2 . Assume the size of the clusters are n1 and n2 respectively. We compute the Mahalanobis distance d12 between the clusters as follows:

$$\Sigma = ((n1 - 1) * \Sigma_1 + (n2 - 1) * \Sigma_2) / (n1 + n2 - 2)$$

$$d12 = \sqrt{t(\mu_1 - \mu_2) * \Sigma^{-1} * (\mu_1 - \mu_2)}$$

The dimension of the clusters must be same.

Value

mahalanobis.dist returns a numeric value measuring the Mahalanobis distance between a pair of normally distributed clusters.

match.clusters

Matching of clusters/meta-clusters across FC samples/templates

Description

This function computes a matching of cluster/meta-clusters across a pair of FC samples/templates. A cluster (meta-cluster) from a sample (template) can match to zero, one or more than one clusters (meta-clusters) in another sample (template).

Usage

```
match.clusters(object1, object2, dist.type='Mahalanobis', unmatched.penalty=999999)

match.clusters.dist(d.matrix, unmatched.penalty=999999)
```

Arguments

<code>object1</code>	an object of class <code>ClusteredSample</code> or <code>Template</code> .
<code>object2</code>	an object of class <code>ClusteredSample</code> or <code>Template</code> .
<code>dist.type</code>	character, indicating the method with which the dissimilarity between a pair of clusters (meta-clusters) is computed. Supported dissimilarity measures are: 'Mahalanobis', 'KL' and 'Euclidean', with the default is set to 'Mahalanobis' distance.
<code>d.matrix</code>	a matrix used only in the second definition (<code>match.clusters.dist</code>) of the function. <code>d.matrix</code> stores the dissimilarities between each pair of clusters (meta-clusters) across a pair of samples (templates) S1 and S2. (i, j) entry of the matrix stores dissimilarity between i -th cluster (meta-cluster) from S1 and the j -th cluster (meta-cluster) from S2. <code>d.matrix</code> can be computed using function <code>dist.matrix</code>
<code>unmatch.penalty</code>	numeric value denoting the penalty for leaving a cluster (meta-cluster) unmatched. This parameter should be already known or be estimated empirically estimated from data (see the reference for a discussion). Default is set to a very high value so that no cluster (meta-cluster) remains unmatched.

Details

We used a robust version of matching called Mixed Edge Cover (MEC) to match clusters (meta-clusters) across a pair of samples (templates). MEC allows a cluster (meta-cluster) to be matched with zero, one or more than one clusters (meta-clusters) across a pair of samples (template). The cost of an MEC solution is equal to the summation of dissimilarities of the matched clusters (meta-clusters) and penalty for the unmatched clusters (meta-clusters). The MEC algorithm finds an optimal solution by minimizing the cost of MEC.

Value

`match.clusters` returns an object of class `ClusterMatch` representing matching of clusters (meta-clusters) across a pair of FC samples (templates). A cluster (meta-cluster) from a sample (template) can match to zero, one or more than one cluster (meta-clusters) in another sample (template).

MetaCluster-class	<i>MetaCluster: An S4 class representing a meta-cluster (collection of biologically similar clusters).</i>
-------------------	--

Description

An object of class "MetaCluster" represents a collection of biologically similar clusters from a set of FC samples. A meta-cluster is formed by matching clusters across samples and merging the matched clusters. An object of class "ClusteredSample" stores the estimated parameter of the whole meta-cluster as well as a list of clusters participating in the meta-cluster.

Creating Object

An object of class `MetaCluster` is usually created when constructing an object of class `Template`. Unless you know exactly what you are doing, creating an object of class "MetaCluster" using `new` or using the constructor is discouraged.

An object of class "MetaCluster" can be created using the following constructor

`MetaCluster(clusters)` where the argument "clusters" is a list of object of class `Cluster` from which the meta-cluster is created.

Slots

An object of class "MetaCluster" contains the following slots:

The number of clusters in the meta-cluster.

`num.clusters` A list of length `num.clusters` storing the clusters (cell populations) participating in this meta-cluster. Each cluster is stored as an object of class `Cluster`.

`size` Number of cells in the meta-cluster (summation of all cluster sizes).

`center` A numeric vector denoting the center of the meta-cluster.

`cov` A matrix denoting the covariances of the underlying normal distribution of the meta-cluster.

Accessors

All the slot accessor functions take an object of class `MetaCluster`. I show usage of the first accessor function. Other functions can be called similarly.

The number of cells in the meta-cluster (summation of all cluster sizes).

Usage: `get.size(object)`

here `object` is a `MetaCluster` object.

`get.size`: `num.clusters` Returns the number of clusters in the meta-cluster.

`get.clusters` Returns the list of clusters (cell populations) participating in this meta-cluster. Each cluster is stored as an object of class `Cluster`.

`get.size` Returns the number of cells in the meta-cluster (summation of all cluster sizes).

`get.center` Returns the center of the meta-cluster.

`get.cov` Returns the covariances matrix of the meta-cluster.

Methods

show Display details about the `Metacluster` object.

summary Return descriptive summary for the `MetaCluster` object.

Usage: `summary(MetaCluster)`

plot We plot a meta-cluster as a contour plot of the distribution of the underlying clusters or the combined meta-cluster. We consider cells in clusters or in the meta-cluster are normally distributed and represent the distribution with ellipsoid. The axes of an ellipsoid is estimated from the eigen values and eigen vectors of the covariance matrix ("Applied Multivariate Statistical Analysis" by R. Johnson and D. Wichern, 5th edition, Prentice hall). We then plot the

bi-variate projection of the ellipsoid as 2-D ellipses.

Usage:

```
plot(mc, alpha=.05, plot.mc=FALSE, ...)
```

the arguments of the plot function are:

- `mc` An object of class `MetaCluster` for which the plot function is invoked.
- `alpha` $(1-\alpha)*100\%$ quantile of the distribution of the clusters or meta-cluster is plotted.
- `plot.mc` TRUE/FALSE, when TRUE the functions draws contour of the combined meta-cluster and when FALSE the function draws the contours of the individual clusters.
- ... Other usual plotting related parameters.

```

symmetric.KL

Symmetrized Kullback-Leibler divergence

Description

Compute the Symmetrized Kullback-Leibler divergence between a pair of normally distributed clusters.

Usage

```
symmetric.KL(mean1, mean2, cov1, cov2)
```

Arguments

mean1	mean vector of length p for cluster 1, where p is the dimension of the clusters.
mean2	mean vector of length p for cluster 2.
cov1	pxp covariance matrix for cluster 1.
cov2	pxp covariance matrix for cluster 2.

Details

Consider two p-dimensional, normally distributed clusters with centers μ_1, μ_2 and covariance matrices Σ_1, Σ_2 . We compute the KL divergence d_{12} between the clusters as follows:

$$d_{12} = 1/4 * (t(\mu_2 - \mu_1) * (\Sigma_1^{-1} - 1) + \Sigma_2^{-1} - 1) * (\mu_2 - \mu_1) + trace(\Sigma_1/\Sigma_2 + \Sigma_2/\Sigma_1) + 2p)$$

The dimension of the clusters must be same.

Note that KL-divergence is not symmetric in its original form. We converted it symmetric by averaging both way KL divergence. The symmetrized KL-divergence is not a metric because it does not satisfy triangle inequality.

Value

symmetric.KL returns a numeric value measuring the Symmetrized Kullback-Leibler divergence between a pair of normally distributed clusters.

Template-class	<i>Template: An S4 class representing a template of a group of FC Samples.</i>
----------------	--

Description

An object of class "Template" summarizes a group of samples belonging to same biological-class with a class-template. A template is represented by a collection of meta-clusters ([MetaCluster](#)) created from samples of same class. An object of class "Template" therefore stores a list of [MetaCluster](#) objects and other necessary parameters.

Creating Object

An object of class "Template" can be created using the function `create.template` :

```
create.template(clustSamples, dist.type = "Mahalanobis", unmatched.penalty=999999, template.id = NA_integer_).
```

The arguments to the `create.template` function is described below:

- `clustSamples`: A list of [ClusteredSample](#) objects from which the template is created. The working examples describe how this objects are created by clustering FC samples.
- `dist.type`: character, indicating the method with which the dissimilarity between a pair of clusters is computed. Supported dissimilarity measures are: 'Mahalanobis', 'KL' and 'Euclidean'. If this argument is not passed then 'Mahalanobis' distance is used by default.
- `unmatched.penalty`: A numeric value denoting the penalty for leaving a cluster unmatched. This parameter should be already known or be empirically estimated from data (see the reference for a discussion). Default is set to a very high value so that no cluster remains unmatched.
- `template.id`: integer, denoting the index of the template (relative to other template). Default is `NA_integer_`

Slots

`num.metaclusters`: The number of meta-clusters in the template.

`metaClusters`: A list of length `num.metaclusters` storing the meta-clusters. Each meta-cluster is stored as an object of class [MetaCluster](#).

`dimension`: Dimensionality of the samples from which the template is created.

`size`: Number of cells in the template (summation of all meta-cluster sizes).

`tree`: A list (similar to an `hclust` object) storing the hierarchy of the samples in a template.

`template.id`: integer, denoting the index of the template (relative to other templates). Default is `NA_integer_`

Accessors

All the slot accessor functions take an object of class `Template`. I show usage of the first accessor function. Other functions can be called similarly.

Number of cells in the template (summation of all meta-cluster sizes).

Usage: `get.size(object)`

here `object` is a `Template` object.

`get.size()`: `num.metaclusters`: Returns the number of meta-clusters in the template.

`get.metaClusters`: Returns a list of length `num.metaclusters` storing the meta-clusters. Each meta-cluster is stored as an object of class `MetaCluster`.

`get.dimension`: Returns the dimensionality of the samples from which the template is created.

`get.tree`: Returns a `hclust` object storing the hierarchy of the samples in a template.

`get.template.id`: Returns the index of the template (relative to other templates).

Methods

show Display details about the `Template` object.

summary Return descriptive summary for each `MetaCluster` of a `Template`.

Usage: `summary(Template)`

plot We plot a template as a collection of bivariate contour plots of its meta-clusters. To plot each meta-cluster we consider the clusters within the meta-cluster normally distributed and represent each cluster with an ellipsoid. The axes of an ellipsoid is estimated from the eigen values and eigen vectors of the covariance matrix of a cluster ("Applied Multivariate Statistical Analysis" by R. Johnson and D. Wichern, 5th edition, Prentice hall). We then plot the bivariate projection of the ellipsoid as 2-D ellipses.

Usage:

`plot(template, alpha=.05, plot.mc=FALSE, color.mc=NULL, colorbysample=FALSE, ...)`

the arguments of the plot function are:

- `template`: An object of class `Template` for which the plot function is invoked.
- `alpha`: $(1-\alpha)*100\%$ quantile of the distribution of the clusters or meta-cluster is plotted.
- `plot.mc`: TRUE/FALSE, when TRUE the functions draws contour of the combined meta-cluster and when FALSE the function draws the contours of the individual clusters.
- `color.mc`: A character vector of length `num.metaclusters` denoting the colors to be used to draw the contours. The *i*th color of this vector is used to draw the ellipses denoting clusters in the *i*th meta-cluster or the combined *i*th meta-cluster (depending on the argument `plot.mc`). By default an empty vector is passed and then an arbitrary color is used to draw each meta-cluster.
- `colorbysample`: TRUE/FALSE, when TRUE the functions draws clusters from same samples in a single color and when FALSE the function draws meta-clusters in a single color.
- ... : Other usual plotting related parameters.

template.tree Plot the hierarchy of samples established while creating the template-tree. See [template.tree](#)
